DESCRIPTION

The authors illustrate the case of a woman in her 80s with history of systemic lupus erythematosus and Sjögren syndrome. She had lost medical follow-up with her rheumatologist in the last 3 years due to progressive functional and cognitive impairment but she was still taking prednisolone 5 mg per day and hydroxychloroquine 400 mg per day for, at least, the past 11 years. She was admitted in the internal medicine ward for an acute medical condition unrelated to the present report. The physical examination was remarkable for skin changes: brown to grey or black reticulated macules on the face and confluent patches on the anterior side of legs and forearms (figure 1A–C), mainly in areas of previous bruising; there was no involvement of the mucous membranes or nail bed. The previous ophthalmological examination had been made 3 years before and there was no sign of retinal involvement. A skin biopsy was performed and showed pigment deposition in superficial dermis with haemosiderin characteristics—Perls Prussian staining was positive for iron and Fontana-Masson staining was negative for melanin. This skin hyperpigmentation was identified as a hydroxychloroquine adverse effect based on ongoing exposure and the drug was suspended; unfortunately it was not possible to see an improvement due to early death of the patient.

The long-term use of hydroxychloroquine in systemic lupus erythematosus treatment is associated with skin lesions in about 7%–29% of the patients.1 2 It usually involves the oral mucosa, shins, nails, forearms and anterior side of the legs.1 2 The time of onset ranges from a few months to years after starting treatment, opposite to the ophthalmological adverse effects that are associated with duration and cumulative dose of hydroxychloroquine. Although the mechanism for hyperpigmentation is still poorly understood, there are some risk factors to consider, most of them related to easy bruising conditions, such as: use of anticoagulants or antiplatelet agents, prolonged use of corticosteroids, skin trauma or antiphospholipid syndrome.1 3 The skin biopsy usually shows melanin granules and haemosiderin deposits with an elevated iron skin concentration, leading to believe that this discoloration usually occurs in areas of previous bruising.1 2

The only treatment for this skin hyperpigmentation is discontinuing hydroxychloroquine, but it can take several months to improve the skin changes. Complete clearance is rare.2

Learning points

► Although hydroxychloroquine toxicity is more known as affecting the eyes, it is also associated with skin hyperpigmentation regardless of the duration of the treatment.

► The main risk factors are conditions that lead to easy bruising; the skin biopsy usually shows deposits of iron and melanin found in previous ecchymotic areas.

► Stop the intake of hydroxychloroquine is the treatment of choice, though it may only ameliorate the skin lesions but never completely solve them.

Contributors RMMDGI was one of the doctors who assisted the patient during this case, gather the information, obtained the images and wrote the text. RR and CAL were also part of the team who observed the patient and revised the text written by the corresponding author.

Funding The authors have not declared a specific grant for this research from any funding agency in the public, commercial or not-for-profit sectors.

Competing interests None declared.

Patient consent Not required.

Provenance and peer review Not commissioned; externally peer reviewed.
