CASE REPORT

Preoperative administration of propranolol reduced the surgical risks of PHACES syndrome in a 14-month-old girl

SUMMARY

PHACES syndrome is an uncommon neurocutaneous disorder first identified in 1996. Patients with PHACES syndrome often require surgical treatment for their anomalies, including intracranial vasculopathy, coarctation/interruption of the aorta, intracardiac defects, glaucoma/cataract and sternal defects. Risk factors associated with the symptoms of intraoperative/perioperative management include ischaemic stroke due to the cerebral vasculopathy, airway obstruction due to the subglottic/tracheal haemangiomas and massive bleeding due to the large haemangiomas. Recently, propranolol is considered as first-line therapy for patients with infantile haemangiomas (IHs). However, until now, there have been no reported cases of PHACES syndrome treated by propranolol to reduce the surgical risks associated with IH. In this report, we describe a case of a 14-month-old Japanese girl with PHACES syndrome treated by propranolol for IH before surgical closure of the ventricular septum defect. Oral administration of propranolol was effective in decreasing the size of IH, leading to the uneventful perioperative course.

BACKGROUND

PHACES syndrome is an uncommon neurocutaneous disorder first identified by Frieden *et al* in 1996.¹ PHACES syndrome includes posterior fossa malformations, segmental haemangiomas of the face, arterial anomalies, coarctation of the aorta/cardiac defects, eye abnormalities, sternal cleft and/or supraumbilical raphe.² Patients with PHACES syndrome often require surgical treatment for their anomalies,² including intracranial vasculopathy, coarctation/interruption of the aorta, intracardiac defects, glaucoma/cataract and sternal defects.³ Risk factors associated with the symptoms of intraoperative/perioperative management include ischaemic stroke due to the cerebral vasculopathy,⁴ airway obstruction due to the subglottic/tracheal haemangiomas⁵ and massive bleeding due to the large haemangiomas.⁶ In 2008, a non-selective β -blocker, propranolol, was reported to attenuate severe infantile haemangioma (IH)⁷ and is now considered as first-line therapy for patients with IH.² However, until now, there have been no reported cases of PHACES syndrome treated by propranolol to reduce the surgical risks associated with IH. Here, we describe a case of a 14-month-old Japanese girl with PHACES syndrome treated by propranolol for

IH before surgical closure of the ventricular septum defect (VSD). Oral administration of propranolol was effective in decreasing the IH, leading to the uneventful perioperative course.

CASE PRESENTATION

A 14-month-old Japanese girl was admitted to our hospital to undergo surgical closure of a VSD. She was born at a regional hospital as a dichorionic diamniotic twin at 36 weeks gestation with a birth weight of 1900 g. At birth, she had a small area of erythema on her right preauricular and upper lip area, which grew into a segmental haemangioma (figure 1A, left) within 3 weeks. A VSD was detected on a transthoracic echocardiogram (figure 1B). She was referred to our university hospital from the regional hospital for management of the growing haemangioma and VSD.

INVESTIGATIONS

MRI revealed cervical haemangioma and hypoplasia of the right cerebellar hemisphere without any signs of subglottic/tracheal haemangiomas (figure 2A). No cerebral arterial abnormalities were found by MRI angiography (figure 2B). She also showed sternal hypoplasia. Considering the combination of the segmental face haemangioma >5 cm (major criterion), posterior fossa malformations (major criterion), intracardiac anomaly (minor criterion) and sternal dysplasia (major criterion), we diagnosed her with definite PHACES syndrome.²

TREATMENT

For treatment of the facial and cervical haemangiomas, oral administration of propranolol was started at 0.5 mg/kg/day and was gradually increased to 2.5 mg/kg/day without any adverse reactions. Repeated MRI at 2 weeks (figure 2C) and 7 months (figure 2D) after the initial treatment showed a significant reduction in the size of the cervical haemangioma. The size and colouring of the facial haemangioma were also markedly reduced within 7 months (figure 1A, middle). At 12 months of age, surgical closure of the VSD was planned based on the results from a right cardiac catheterisation, which showed a mean pulmonary arterial pressure of 32 mm Hg and a pulmonary to systemic flow ratio of 2.2.

On admission at 14 months old, the patient weighed 7170 g (−2.3 SD) and was 70.8 cm (−1.8 SD) tall (figure 1C shows a growth chart). There were residual

(B) Transthoracic echocardiogram at 14 months shows perimembranous VSD. (C) A growth chart with centiles in the patient.

small haemangiomas on her right preauricular and upper lip area (figure 1A, right). A systolic murmur, classified as grade III/VI according to Levine's grading system, was audible at the left second parasternal area. The patient did not have audible rales, and her mental and physical development was within the normal range. The laboratory tests revealed a relatively low haemoglobin level (106 g/L) with a normal platelet count ($556 \times 10^9/\text{L}$) and normal coagulation score. The hormonal examination results showed no evidence of endocrinological diseases. MRI revealed a further reduction in the size of cervical haemangioma (figure 2E).

The VSD closure was performed under general anaesthesia without any complication, including ischaemic stroke, airway obstruction or massive bleeding of haemangioma. Total cardiopulmonary bypass (CPB) was done in 103 min with 49 min of aortic cross clamping.

OUTCOME AND FOLLOW-UP

The patient was safely extubated on the day of surgery. The perioperative course was uneventful without any growth of facial haemangioma nor any neurological complications, such as convulsion, paralysis or altered level of consciousness. In addition, MRI performed 10 days after surgery showed that the size

of the cervical haemangioma did not increase (figure 2F) and that there were no signs of brain ischaemia. The patient was discharged from our facility on postoperative day 11.

DISCUSSION

The prognosis of patients with PHACES syndrome is variable and depends on comorbidities, such as IH and cardiovascular and/or cerebral artery abnormalities. Since patients with PHACES syndrome frequently require surgery for comorbidities, it is critically important to evaluate perioperative risk factors, including anaesthetic management and postoperative care. Severe IH has been reported to cause life-threatening events, including airway obstruction due to oropharyngeal IH,⁵ ulceration and massive bleeding of the large segmental IH⁶ and disseminated intravascular coagulation due to a large visceral IH that grew larger after cardiac surgery with CPB.⁸ These events may have been avoidable if the severe IH had been reduced before surgery. In our case, we treated the patient with propranolol preoperatively to reduce the size of the large IH and safely performed cardiac surgery with CPB. We believe that propranolol treatment for severe IH is one strategy to reduce the predicted perioperative risks of PHACES syndrome or other diseases with large IH.

In contrast, several side effects of propranolol treatment for IH have been reported, including hypotension, bradycardia, hypoglycaemia, hypokalaemia, bronchoconstriction, stroke and ischemia, due to decreased arterial perfusion pressure.⁴ In patients with PHACES syndrome and cerebral arterial abnormalities, it is especially important to maintain cerebral perfusion pressure. Furthermore, perioperative physiological stress is a potential risk factor for strokes and seizures. It is essential to examine cerebral arterial abnormalities, including cerebral perfusion, and to check the endocrinological status, including thyroid function, glucose tolerance and electrolyte balance, before starting propranolol for IH. Appropriate guidelines for the perioperative management of patients with PHACES syndrome are needed.

In conclusion, we treated a patient with PHACES syndrome and severe IH with propranolol, which resulted in a prominent reduction of the IH. The perioperative course of the subsequent intracardiac repair surgery was safe and uneventful.

Learning points

- Patients with PHACES syndrome often require surgical treatment for their anomalies.
- Preoperative management of severe infantile haemangioma by oral propranolol would reduce the surgical risks of the PHACES syndrome.
