DESCRIPTION

A 47-year-old man with a history of recent root canal treatment on a lower left molar, presented to the Maxillofacial Surgery Department with a 6-month history of left-sided facial pain. This was exacerbated by yawning and radiated to the angle of the mandible. Examination revealed a fullness posterior to the left angle of the mandible but no discrete mass. In light of his recent dental treatment, an orthopantomogram was obtained to exclude a dental cause for the symptoms. This demonstrated a small periapical pathology associated with the lower left molar, in keeping with recent treatment. The possibility of a calcified left stylohyoid ligament was raised; however, this was deemed to be likely artifactual. Parotid ultrasound was unremarkable.

Referral was subsequently made to the Otorhinolaryngology Department for further assessment. Here it was found that the patient's symptoms could be reproduced by digital palpation within the left tonsillar fossa. A CT scan of the neck demonstrated an enlarged left styloid process with calcification of the stylohyoid ligament, characteristic of Eagle syndrome (figures 1 and 2). The patient underwent a left neck exploration with styloidectomy. The specimen was 7.5 cm long and contained interrupted segments of the mineralised ligament (creating the appearance of multiple pseudoarticulations, a type

III elongated styloid).¹ Recovery was unremarkable and the patient's symptoms resolved.

Eagle syndrome is the symptomatic elongation of the styloid process or calcification of the stylohyoid ligament. The length of the styloid process varies, however 30 mm is thought to be the upper limit of normal.²

Several theories for Eagle syndrome have been proposed: (1) surgical trauma or local chronic irritation causing reactive ossifying hyperplasia within the stylohyoid complex; (2) reactive metaplasia secondary to the healing response to trauma and (3) normal anatomical variance.³

Eagle syndrome may present with the classic features of facial/oropharyngeal pain exacerbated by head movement, globus sensation, dysphagia and otalgia. However, carotid artery and jugular vein variants have been described.⁴ The carotid variant results from the elongated styloid impinging the carotid artery causing carotid dissection, transient ischaemic attacks or impairment of sympathetic innervation.⁴ The jugular vein variant is associated with headache and dizziness, probably due to reduced cerebral venous

flow. Furthermore, the jugular variant has been reported to be associated with idiopathic intracranial hypertension and perimesencephalic subarachnoid haemorrhage, both potentially a result of intracranial venous hypertension secondary to jugular impingement.^{4 5}

The variation in presentation combined with the low incidence makes Eagle syndrome a diagnostic challenge. The differential diagnosis includes glossopharyngeal or sphenopalatine neuralgia, temporal arteritis, migraine, temporomandibular joint dysfunction, impacted molar teeth and myofascial pain dysfunction.

Learning points

- Oro-facial and neck pain has a wide differential diagnosis and the possibility of Eagle syndrome should be considered.
- Careful palpation of the tonsillar fossa may reveal a bony hard swelling and reproduce the symptoms.
- Arterial and venous narrowing should be investigated in cases of Eagle syndrome.
- Panoramic or cross-sectional imaging will confirm the diagnosis and aid surgical planning.

Diagnosis is based on clinical suspicion and is confirmed by imaging. Treatment can be surgical or non-surgical. Non-surgical options include anti-inflammatory medications and local anaesthetic injections into the tonsillar fossa. Surgical treatment requires styloidectomy which may be via an intra-oral or trans-cervical approach.

Contributors AG and AS were involved with writing the report. BA reconstructed the CT images and AC edited the manuscript.
