A rare case of biventricular non-compaction

DESCRIPTION

A 59-year-old man with a history of chronic obstructive pulmonary disease (COPD) presented with progressive dyspnoea and bilateral leg swelling over 3–4 weeks. He had dyspnoea on moderate exertion at the baseline but progressed to symptoms at rest along with new onset of orthopnoea. He reported no chest pain, palpitations, syncope, fever, chills, wheezing or productive cough. His mother and brother died at ages 54 and 44, respectively, after developing heart failure of unknown aetiology. He has a smoking history of 40 pack-year. His physical examination on admission revealed stable vitals, elevated jugular venous pulse (JVP), normal S1 and S2 sounds, regular heart rate, no murmur, rubs or gallop, diminished breath sounds in bilateral bases with occasional wheezing and bibasilar rales. His lower extremities revealed bilateral 1+ non-tender pitting oedema with clubbing.

The electrocardiogram showed sinus tachycardia with a right axis deviation with evidence of left ventricular hypertrophy and right atrial enlargement. There were no ischaemic changes. Chest X-ray (CXR) was normal. An echocardiogram showed global hypokinesia with a left ventricular ejection fraction of 35%–40% with grade I diastolic dysfunction and probable non-compaction of the left ventricle (figures 1 and 2). Right ventricular function and right ventricular systolic pressure were normal. A provisional diagnosis of left ventricular non-compaction (LVNC) was made. He was started on furosemide, lisinopril and carvedilol. Bilateral cardiac catheterisation showed normal coronary arteries with elevated pulmonary wedge pressure consistent with non-ischaemic cardiomyopathy. Cardiac MRI confirmed increased trabeculation in both ventricular apices with impaired biventricular systolic function confirming biventricular non-compaction (BVNC) cardiomyopathy (figures 3–5).

Non-compaction is thought to be due to intrauterine arrest of compaction of the loose interwoven meshwork present in fetal myocardial primordium.1 2 Alternatively, the pronounced hypertrabeculation may be due to altered regulation in cell proliferation, differentiation and maturation during ventricular wall formation.1 2 Clinically, it may have variable manifestations of heart failure, chest pain, thromboembolic events, atrial and ventricular arrhythmias and risk of sudden cardiac arrest.1 2 It is recommended to undergo Holter monitoring to screen for arrhythmias as there is a role of an implantable cardioverter-defibrillator (ICD).1 Oral anticoagulation is recommended if there is arrhythmia, atrial or ventricular thrombi or for primary prevention of thrombus in case of left ventricular (LV) dysfunction.1 Our patient presented...
due to non-family history of heart failure of unknown aetiology was likely medical follow-up. Holter monitor did not reveal any arrhythmias and he did not improve symptomatically with medical therapy and continues to be in the follow-up. In our patient, we can speculate that the family history of heart failure and sudden cardiac death.

Echocardiography is used both to establish the diagnosis of non-compaction cardiomyopathy and as an aid during follow-up. Jenni et al proposed the following three criteria for diagnosis: (1) a thickened left ventricular wall composed of two layers: a thin compacted epicardial layer and a non-compacted endocardial layer with numerous prominent trabeculations and deep recesses; a maximum ratio of non-compacted to compacted myocardium being >2:1 at end systole in the parasternal short-axis view, (2) colour Doppler evidence of flow within the deep intertrabecular recesses and (3) prominent trabecular meshwork in the left ventricular (LV) apex or midventricular segments of the inferior and lateral wall.

Cardiac MRI (CMR) criteria for LVNC are still evolving. The following end-diastolic and end-systolic CMR criteria have been proposed as per various studies conducted so far: (1) A maximum end-diastolic non-compacted to compacted myocardial thickness ratio of >2.3 was the best criterion for LVNC and yielded a sensitivity of 86% and specificity of 99% for LVNC. (2) A trabeculated LV mass > 20% of global LV mass was identified as a criterion for LVNC with a sensitivity of 94% and a specificity of 94%. (3) Fractal dimension as a quantitative measure of trabeculation is high in LVNC and may be very accurate; however, further follow-up is needed to better identify its role. (4) An end-systolic non-compacted to compacted (thickness) ratio > 2.0 was found to be more strongly associated with heart failure and with adverse events (heart failure, death, heart failure readmission, embolic events and ventricular arrhythmias) than other criteria for LVNC.

Learning points

- Isolated ventricular non-compaction can be sporadic or familial and is characterised by prominent trabeculae and deep intertrabecular recesses. Left ventricular non-compaction (LVNC) has been found in 0.014%–1.3% of patients undergoing echocardiography (biventricular non-compaction being even rarer), and it is an uncommon cause of heart failure and sudden cardiac death.

- Echocardiography is used both to establish the diagnosis of non-compaction cardiomyopathy and as an aid during follow-up. Jenni et al proposed the following three criteria for diagnosis: (1) a thickened left ventricular wall composed of two layers: a thin compacted epicardial layer and a non-compacted endocardial layer with numerous prominent trabeculations and deep recesses; a maximum ratio of non-compacted to compacted myocardium being >2:1 at end systole in the parasternal short-axis view, (2) colour Doppler evidence of flow within the deep intertrabecular recesses and (3) prominent trabecular meshwork in the left ventricular (LV) apex or midventricular segments of the inferior and lateral wall.

- Cardiac MRI (CMR) criteria for LVNC are still evolving. The following end-diastolic and end-systolic CMR criteria have been proposed as per various studies conducted so far: (1) A maximum end-diastolic non-compacted to compacted myocardial thickness ratio of >2.3 was the best criterion for LVNC and yielded a sensitivity of 86% and specificity of 99% for LVNC. (2) A trabeculated LV mass > 20% of global LV mass was identified as a criterion for LVNC with a sensitivity of 94% and a specificity of 94%. (3) Fractal dimension as a quantitative measure of trabeculation is high in LVNC and may be very accurate; however, further follow-up is needed to better identify its role. (4) An end-systolic non-compacted to compacted (thickness) ratio > 2.0 was found to be more strongly associated with heart failure and with adverse events (heart failure, death, heart failure readmission, embolic events and ventricular arrhythmias) than other criteria for LVNC.
