SUMMARY

Dopamine supersensitivity psychosis (DSP) frequently arises with long-term antipsychotic treatment and accounts for a significant proportion of treatment-resistant schizophrenia. The mechanism underlying DSP is thought to be a compensatory increase in dopamine receptor density in the striatum caused by long-term antipsychotic treatment. Previous animal studies have reported that antipsychotics increase serotonin 5-HT_{2A} receptor density in the striatum and that 5-HT_{2A} receptor blockers suppress dopamine-sensitive psychomotor activity, which may be linked to the pathophysiology of DSP. In this paper, we describe a patient who was hospitalised with treatment-resistant schizophrenia. Following treatment with high-dose antipsychotic polypharmacy for 10 weeks, the patient experienced worsening of psychotic and extrapyramidal symptoms. The patient was then started on second-generation antipsychotic asenapine while other antipsychotics were tapered off, resulting in improvement of these symptoms. Retrospectively, we presumed that the high-dose antipsychotic polypharmacy caused DSP, which was effectively treated by the potent 5-HT_{2A} receptor antagonism of asenapine.

BACKGROUND

Antipsychotics play a crucial role in the treatment of psychotic disorders, such as schizophrenia. However, their administration requires close monitoring because of their potential to induce a variety of adverse events, which include exacerbation of psychotic symptoms and side effects, such as drug-induced parkinsonism. Of note, dopamine supersensitivity psychosis (DSP) is thought to explain the phenomenon in which patients often relapse following slight dose reductions, discontinuation or switching of antipsychotics. Chouinard *et al* estimated that 50% of treatment-resistant schizophrenia cases are related to DSP.¹ A possible mechanism is that long-term antipsychotic treatment causes a compensatory increase in dopamine receptor density in the striatum, which leads to a dopamine supersensitive state.^{2–5} Moreover, recent studies have shown that the prevalence rate of DSP in patients with treatment-resistant schizophrenia in Japan is as high as 70%.⁶ The differences in the proportions of patients with DSP may be explained by the common use of high-dose antipsychotic polypharmacy in Japan.^{5,7} From the perspective of treatment strategies for DSP, one possible molecular mechanism involves the interaction between

dopaminergic and serotonergic neurotransmission. Previous animal studies have reported that antipsychotics increase receptor density of serotonin 5-HT_{2A}, a serotonergic receptor subtype, in the striatum and that 5-HT_{2A} receptor antagonists suppress dopamine-sensitive psychomotor activity, which may be linked to the pathophysiology of DSP.⁸ We report a case of a male patient with schizophrenia, who developed DSP following high-dose antipsychotic polypharmacy. Symptoms improved following treatment with asenapine, an atypical antipsychotic that has high 5-HT_{2A} antagonist binding potential.

CASE PRESENTATION

Mr A, a single man aged 44 years, suddenly ran outdoors 13 years earlier with the belief that he was contacting his old friend telepathically. He was referred to our hospital that year and we observed symptoms of delusions, hallucinations and cataplexy. His previous medical history included purulent meningitis in infancy, hyperlipidaemia, hyperuricaemia, hypertension and obesity.

TREATMENT

He was diagnosed with schizophrenia (ICD-10 code F20.0) and started receiving antipsychotic therapy at our hospital. He was prescribed maximum doses of risperidone, olanzapine, quetiapine and aripiprazole at each previous hospitalisation because of a worsening of psychotic symptoms. These maximum doses were taken over to an outpatient setting and gradually reduced to 2 mg/day of risperidone in the last year. He two times experienced rebound psychosis during switching of antipsychotics, 13 and 6 years earlier. The first episode occurred after switching 8 mg/day of risperidone to 20 mg/day of olanzapine and the second after switching 600 mg/day of quetiapine to 20 mg/day of olanzapine, during which oromandibular dyskinesic movement was observed. These symptoms, alongside a history of high-dose antipsychotic medication, suggest DSP at an earlier period. His latest hospital admission was voluntary and was because of a slight irritation (day 0). Because his symptoms were not causing significant distress, he was followed up without any changes in prescription. However, on day 7, he developed prominent thought disorder, delusions of being injured by broken glass and a variety of visual and auditory hallucinations. Therefore, risperidone was increased to 8 mg/day for the following 2 weeks, and quetiapine was initiated at

Figure 1 Reinforcement and replacement of antipsychotic medication worsened psychotic symptoms. Starting asenapine and tapering off other antipsychotics resulted in improvement of psychotic and extrapyramidal symptoms. ASP, asenapine; BRX, brexpiprazole; OLZ, olanzapine; QTP, quetiapine; RIS, risperidone.

200 mg/day (day 17) and slowly increased to 600 mg/day over the next 2 weeks, with an expectation of anxiolytic and sedative drug effects. However, the patients showed inadequate response to these medications. From day 28, risperidone was gradually replaced with olanzapine, and at day 50, olanzapine was increased to 30 mg/day. Despite temporary symptomatic improvement, we observed further aggravation of psychotic symptoms when chlorpromazine equivalence reached 1850 mg (day 59). During the course of the abovementioned antipsychotic medication reinforcement and replacement (figure 1), he developed extrapyramidal symptoms (EPS) of akathisia and stuttering; the latter was suspected to be a tardive dyskinetic movement of the tongue. Given the risk of metabolic side effects and the inadequate sedative effect, quetiapine was tapered and discontinued, while brexpiprazole was gradually increased to 4 mg; however, the patient experienced no symptomatic improvement. We considered using clozapine because the patient met the definition of treatment-resistant schizophrenia, and evidence has suggested that clozapine is the treatment of choice for treatment-resistant schizophrenia.^{9–11} However, the patient's mother did not agree to the administration of clozapine because of fear of side effects, such as agranulocytosis. Finally, he was treated with asenapine, which was initiated at 10 mg/day (day 84) and increased to 20 mg/day (day 93). Olanzapine and brexpiprazole were tapered and discontinued.

OUTCOME AND FOLLOW-UP

Four weeks of treatment of 20 mg/day of asenapine resulted in gradual improvement of psychotic symptoms and EPS. He subsequently willingly participated in an occupational therapy programme and was discharged on day 229.

DISCUSSION

In our patient, increasing antipsychotics worsened psychotic symptoms, which was against our expectations. He fulfilled the clinical characteristics of DSP, as reported by Chouinard *et al*, which are (1) improvement in acute psychotic symptoms, at least initially, by increasing antipsychotic dose, (2) at least 3 months of cumulative exposure to antipsychotics, (3) tolerance to antipsychotic effects, (4) rapid relapse following drug discontinuation, dose reduction or switching of antipsychotics, (5) worsening of psychotic symptoms with life stressors, such as minor life events or daily hassles, (6) appearance of new or more severe psychotic symptoms, (7) treatment resistance and (8) movement disorders, such as tardive dyskinesia.^{5,12} These symptoms were all observed during the most recent hospitalisation. However, his previous

experiences of rebound psychosis and oromandibular dyskinetic movement during switching of antipsychotics suggest that he had developed DSP during an earlier period.

We question whether a period of 4 weeks for improvement of the established DSP state with asenapine was too short. A therapeutic course of several months is usually suggested for clinical cases of treatment-resistant schizophrenia with DSP.¹³ However, an animal study demonstrated rapid (within minutes to an hour) suppression of DSP-like activity using a 5-HT_{2A} antagonist,⁸ which corresponds to several hours in humans.¹⁴ This may explain the rapid therapeutic effect induced by the agent in our patient. In light of this, it is possible that improvement of an established DSP state can be achieved within several days or weeks.

Several human studies have demonstrated that the underlying mechanism of DSP is a compensatory increase in dopamine D₂ receptor density in the striatum caused by long-term administration of antipsychotics.^{4,5} Both lower and higher antipsychotic doses have been shown to induce dopamine supersensitive states in animal studies, but only the higher dose increased the number of striatal D₂ receptors.^{3,15} Moreover, the relationship between DSP and 5-HT_{2A} receptor function has also been demonstrated in an animal study that showed that chronic exposure to antipsychotic medications increases amphetamine-induced locomotion relative to antipsychotic-naïve rats, which is indicative of a dopamine supersensitive state. In contrast, ritanserin and MDL100,907, both 5-HT_{2A} receptor antagonists, suppress locomotion in antipsychotic-treated rats. Additionally, haloperidol was shown to decrease 5-HT_{2A} receptor density in the prelimbic cortex and nucleus accumbens core and increase 5-HT_{2A} receptor density in the caudate-putamen.⁸ It should also be noted that asenapine exhibits the highest affinity for 5-HT_{2A} receptors within second-generation antipsychotics.¹⁶ Given these findings, it is possible that, in our patient, DSP was induced by high-dose antipsychotic polypharmacy, and dopamine sensitivity was reduced by 5-HT_{2A} receptor blockade by asenapine. To date, there has only been one report that suggested a positive effect of asenapine on DSP, which was in a patient with delusional disorder whose DSP was thought to have been induced by ziprasidone.¹⁷

Other than the action on the 5-HT_{2A} system, there are other antipsychotics profiles of note that are closely related to DSP: half-life period, affinity to dopamine D₂ receptors and dopamine partial agonists. First, the instability of drug blood levels accounts for the instability of psychiatric symptoms.⁵ Long half-life period, sustained release or long-acting injectable

antipsychotics are considered to be effective for preventing DSP because of the stability of blood drug levels.¹⁸ Half-life periods of representative antipsychotics are 20 hours for risperidone,¹⁹ 7 hours for quetiapine,²⁰ 33 hours for olanzapine,²¹ 91 hours for brexpiprazole²² and 24 hours for asenapine.²³ Asenapine has the advantage of a longer half-life period than that of risperidone or quetiapine. Second, antipsychotics that have higher affinity to dopamine D2 receptors are presumed to be effective in the treatment of DSP.²⁴ Asenapine has higher affinity to dopamine D2 receptors than that of risperidone, quetiapine or olanzapine.^{11 25–27} Finally, according to animal studies, a dopamine partial agonist is likely to be effective for DSP.^{28 29} However, they may exacerbate psychotic symptoms in cases where DSP has already developed.³⁰ This would explain why brexpiprazole, which is a dopamine partial agonist, was ineffective in our case.

In conclusion, this case presents an important clinical implication for use of antipsychotic agents. Both long-term use as well as high-dose polypharmacy of antipsychotics should be avoided as much as possible because of their potential to cause DSP due to increases in D2 receptor density and changes in 5-HT_{2A} receptor density across various brain regions. Antipsychotics with strong 5-HT_{2A} antagonism may be effective for the treatment of DSP.

Learning points

- This case presents an important clinical implication for the use of antipsychotic agents.
- Both long-term use and high-dose polypharmacy of antipsychotics should be avoided as much as possible because they may cause dopamine supersensitivity psychosis (DSP).
- Antipsychotics with potent 5-HT_{2A} antagonism may be effective for DSP.
