SUMMARY

Ehlers-Danlos syndrome (EDS) causes joint hypermobility and joint dislocation. Since there are no reports of proximal tibiofibular joint (PTFJ) dislocation caused by EDS, little is known about the long-term course of this disease. A woman in her 40s presented with a posterolaterally depressed tibial condyle and severe valgus deformity caused by a long-standing PTFJ dislocation due to EDS. Considering the pathology, posterolateral open-wedge high tibial osteotomy (PLOWHTO) and medial closed-wedge distal femoral osteotomy were performed according to the deformity analysis. A favourable short-term clinical outcome was obtained and the PTFJ dislocation was reduced over time. Although PLOWHTO has several pitfalls, it is a logical and useful surgical technique that can help treat posterolateral dysplasia of the tibial plateau concomitant with severe valgus deformity, regardless of joint laxity, if performed with attention to pitfalls.

BACKGROUND

Ehlers-Danlos syndrome (EDS) is a hereditary disorder that leads to systemic connective tissue fragility, such as in the skin, joints and blood vessel walls, with joint hypermobility, leading to systemic joint dislocations and subsequent osteoarthritis. Although various types of joint dislocations have been reported,¹⁻³ there are no previous reports on proximal tibiofibular joint (PTFJ) dislocations caused by EDS. Here, we report a case of EDS with PTFJ dislocation that led to a severe valgus-aligned knee with posterolateral dysplasia of the lateral tibial condyle.

CASE PRESENTATION

A woman in her early 40's, who suffered a severe valgus deformity with PTFJ dislocation in her left knee, was referred to our hospital. Her left knee pain gradually worsened with time after undergoing a lateral meniscectomy 10 years ago. She had no symptoms of swelling, clicking, catching or limitation in her range of motion, but her quality of life was severely limited by the impairment of

weight-bearing caused by the excessive valgus of the knee with hyperextension (table 1).

All conservative treatments, such as insole therapy and steroid injection, offered at several hospitals had failed.

Hyperextension of both knees, elbows, wrists and fingers was observed (figure 1), and the Beighton criteria showed a score of 8 out of 9.⁴ In addition to PTFJ dislocation, she had severe scoliosis, a history of patellar dislocation and a family history of joint hypermobility, which may suggest a genetic predisposition. Based on these findings, we clinically diagnosed her condition as EDS, despite the lack of biochemical and/or molecular analysis due to her refusal.

INVESTIGATIONS

Plain radiographs and CT revealed that the fibular head was dislocated, and the tibial condyle unsupported by the fibula was depressed posterolaterally (figure 2A,B,E,G,H). The lateral view of CT showed a steep lateral tibial posterior slope at an angle of 17° (Figure 5E). MRI demonstrated that the middle part of the lateral meniscus was almost completely resected (figure 2C,D). A radiograph of the anteroposterior view of the whole leg in the standing position showed that the mechanical lateral distal femoral angle (mLDFA, reference values: 85°–90°)⁵ and mechanical medial proximal tibial angle (mMPTA, reference values: 85°–90°)⁵ were 85° and 100°, respectively. The weight-bearing line (WBL) ratio⁶ was 130%, demonstrating severe valgus alignment. The major cause was a deformity of the proximal tibia with a mild deformity of the distal femur (figure 2F).

Based on the deformity analysis, we performed preoperative planning. The target mechanical axis was planned as the postoperative WBL ratio passed through 50% from the medial edge of the tibial plateau. Accordingly, the correction angle was planned to be 6° by medial closed-wedge distal femoral osteotomy (MCWDFO) and 8° by posterolateral open-wedge high tibial osteotomy (PLOWHTO). The posterior opening distance was calculated to be 8 mm based on a

3-dimensional printed model (ZimmerBiomet G.K., Tokyo, Japan) (figure 2I,J). Although the standard value of the tibial posterior slope is 6° when the posterior cortex is used as a reference line,⁷ the target slope was planned to be around 10° to prevent further hyperextension of the knee.

DIFFERENTIAL DIAGNOSIS

Treatment

The patient was placed in a supine position under general anaesthesia. No tourniquet was used throughout the whole arthroscopy and femoral, fibular and tibial osteotomy procedures. After arthroscopic partial meniscectomy for a flap tear of the posterior segment of the lateral meniscus, a biplanar MCWDFO was performed using a subvastus approach according to the procedure described by Nakamura *et al.*⁸ The osteotomized site was fixed with an MCWDFO-specific

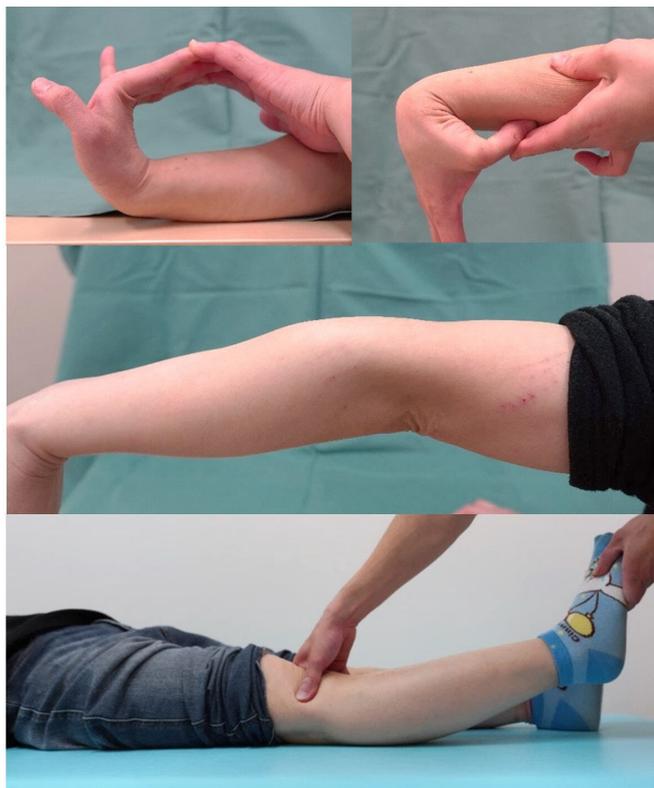

Figure 1 Physical examination demonstrates polyarticular joint hypermobility. The knee and elbow joints show hyperextension by more than 10°. The Beighton diagnostic criteria for EDS show a score of 8 out of 9.⁴ EDS, Ehlers-Danlos syndrome.

locking plate (TriS Medial DFO Plate, Olympus Terumo Biomaterials, Tokyo, Japan). The peroneal nerve was then released through a posterolateral longitudinal skin incision, separate from the incision for the tibial osteotomy, to prevent peroneal nerve palsy by posterolateral opening. The posterolateral incision provided working space for subsequent fibular osteotomy with safe and sufficient retraction of the released nerve. Segmental fibular osteotomy was performed through the same incision immediately below the fibular head (figure 3A,B).

Subsequently, a 10 cm curved longitudinal skin incision was made on the anterolateral aspect of the knee through Gerdy’s tubercle. The tibialis anterior and posterior soft tissues were subperiosteally released. Two Kirschner wires (2.0 mm diameter) were inserted 40 mm distal to the lateral proximal tibial plateau to 15 mm distal to the medial proximal tibial joint surface. A hinge point was set at approximately 5 mm before the medial

tibial cortex. Since PLOWHTO is likely to be unstable following a hinge fracture, the medial plate (TomoFix small version, DePuy Synthes, Bettlach, Switzerland) was temporarily fixed with two Kirschner wires before tibial osteotomy (figure 4A,B). For the medial plating, the anteromedial arthroscopic portal was extended distally by 3 cm and the plate was subcutaneously installed.

A biplanar osteotomy was performed similarly to that of medial open-wedge high tibial osteotomy (OWHTO),⁹⁻¹¹ and the osteotomized site was opened to the planned distance using a spreader. The removed fibula was crushed and used as a gap filler, and two bone-substitute wedges made of beta-tricalcium phosphate (OSferion60 Marvelous; Olympus Terumo Biomaterials, Tokyo, Japan) were inserted between the lateral cortices (figure 4C). Lateral fixation was then performed using an locking compression plate (LCP) proximal lateral tibial plate (DePuy Synthes, Bettlach, Switzerland), and medial plate fixation was completed using locking screws (figure 5A,B). Range of motion exercises were initiated on the first day after surgery, and full weight-bearing was allowed at 6 weeks.

OUTCOME AND FOLLOW-UP

Postoperative radiography of the entire leg revealed an anatomically corrected WBL (51%). mL DFA and mMPTA

were corrected to 91° from 85° and 92° from 100°, respectively. The 3-dimensional CT demonstrated that the lateral tibial posterior slope angle decreased from 17° to 11° after surgery (figure 5E,F). Both coronal and sagittal alignments were maintained for 2 years after surgery (figure 5C,D), and the PTFJ dislocation was reduced over time (figure 5C,D).

At 2 years of follow-up, the patient reported no complaints and showed significant improvement in Knee Injury and Osteoarthritis Outcome Score. The score exceeded the

minimal clinically important difference¹² except for the symptom subscale (table 1).

DISCUSSION

Although there have been reports of dislocation of the hip, patella, shoulder, elbow joints, etc, in patients with EDS,¹⁻³ a case of dislocation of the PTFJ associated with EDS has never been reported. Traumatic PTFJ dislocation in adulthood, although rare,¹³ provides little useful information about the effects of PTFJ dislocation in skeletally immature knees on bony growth and/or bony deformities. From the present case, we found that the dislocation of the fibula, which acts as a supporting strut for the posterolateral part of the tibial condyle,^{14 15} caused dysplasia of the posterolateral tibia, resulting in valgus knee alignment. It is possible that excessive lateral compartment loading exerted a compression force on the distal lateral femur, which also induced a valgus deformity of the distal femur.

In comparison with other syndromic dysplasias of the knee joint such as Blount disease, Turner syndrome or Ellis-van Creveld syndrome, the skin and blood vessels of EDS patients should be treated with special care because of the fragility of the systemic connective tissue. Gentle retraction and careful haemostasis during surgery could be crucial to a successful osteotomy. The use of separate incisions—an anterolateral incision for the tibial osteotomy and a posterolateral incision for the fibular osteotomy/peroneal nerve release—may enhance security. To control bleeding, we used a non-tourniquet procedure under strict blood pressure control (< 100 mm Hg) to ensure that any vascular injury could be detected during surgery, thus mitigating the risk of postoperative haemorrhagic swelling.

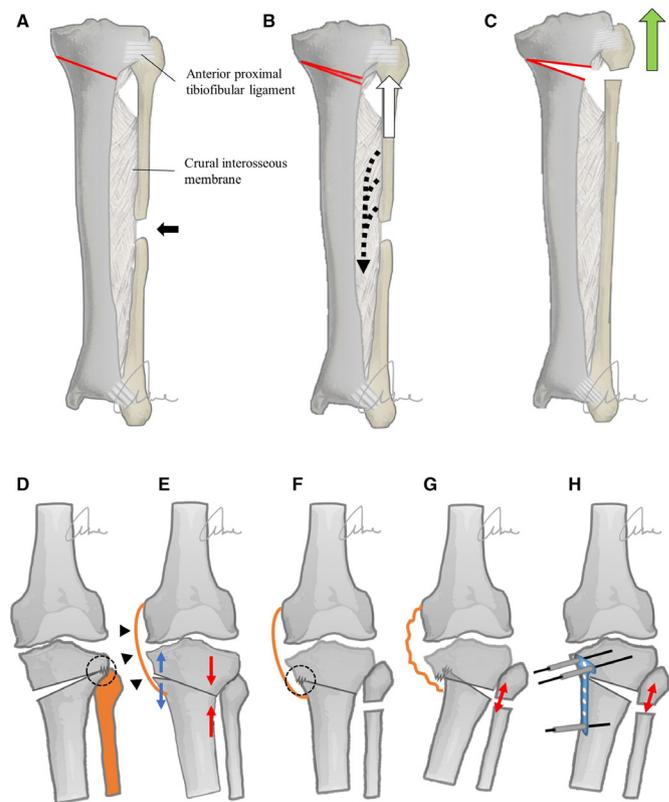

Figure 6 The role of the crural interosseous membrane and the stabilizing effect of each osteotomy. (A) Fibula osteotomy at the midportion and segmental resection (black arrow). (B) In opening the proximal tibia (red lines), the proximal part of the osteotomized fibula requires a proximal migration (white arrow) in synchrony with the tibia. The counterforce by the crural interosseous membrane inhibits the proximal migration of the fibula (black dotted arrow), which makes it difficult to open the gap. (C) The proximal fibular osteotomy immediately below the fibular head enables fibular proximal migration without any interference (green arrow). (D) In medial open-wedge high tibial osteotomy (HTO), the fibula supports the lateral stability when a hinge fracture (dotted circle) occurs. (E) In hybrid closed-wedge HTO, which is combinational HTO of medial open (blue arrows) and lateral close (red arrows), medial collateral ligament acts as tension band (black arrowheads), leading to medial stability. (F) In posterolateral open-wedge HTO, when a hinge fracture (dotted circle) occurs, (G) lateral osteotomized site opening (double-headed arrow) results in medial instability since medial collateral ligament does not act as a medial stabiliser. (H) Temporary fixation on the anteromedial side of the osteotomy provides medial stabilisation and facilitates the posterolateral opening maneuver (double-headed arrow). The figures were drawn by the first author (anonimised for the blinded review).

For patients with Blount disease or Turner syndrome, with severe varus of the knees with a single deformity centre around the medial tibial condyle, surgical correction with a large opening at one time should be avoided. An inverted V-shaped high tibial osteotomy,¹⁶ which can reduce the opening distance, or gradual correction using the hemicallotaxis method,¹⁷ are possible options. For severe and complicated valgus deformity due to Ellis-van Creveld syndrome, two-step correction¹⁸ may be the most reliable procedure. In the current case with EDS, the posterolateral opening distance was decreased by performing an MCWDFO according to the deformity analysis, reducing the

Learning points

- ▶ Proximal tibiofibular joint dislocation due to Ehlers-Danlos syndrome causes dysplasia of the posterolateral tibia, resulting in a severe valgus-aligned knee.
- ▶ Depending on the patient's condition and deformity, extra-articular osteotomy may be helpful in certain cases.
- ▶ In posterolateral open-wedge high tibial osteotomy (PLOWHTO), peroneal nerve neurolysis is necessary to avoid peroneal nerve palsy.
- ▶ PLOWHTO requires fibula osteotomy just below the fibula head to eliminate the effect of crural interosseous membrane stability.
- ▶ In PLOWHTO, anteromedial temporary fixation provides a medial stabilising effect.

risk of complications such as skin laceration, peroneal nerve palsy and/or delayed union.

The efficacy of TKA as a treatment for knee OA and joint instability associated with EDS has been reported previously.¹⁹ However, it has also been reported that postoperative instability can necessitate revision surgery in some cases.^{20, 21} Since the valgus deformity was localised to the proximal tibia in this case, extra-articular osteotomy was a more logical and solution-oriented approach to the problems of joint laxity and deformity correction.

Considering the pathology, the correction osteotomy should be targeted for anatomical alignment. Therefore, we planned (1) the posterolateral opening osteotomy of the tibia and (2) the medial closing osteotomy of the distal femur. Although MCWDFO can be performed in the usual manner, PLOWHTO has several pitfalls.

The important points to be considered when using this technique are as follows: (1) peroneal nerve neurolysis is necessary; (2) fibula osteotomy is performed just below the fibular head and (3) the posterolateral gap is opened after temporary plate fixation of the anteromedial site. Mechanical stretching of the nerve is likely to contribute to nerve injury or ischaemia,^{22, 23} resulting in peroneal nerve palsy. Prior to fibula osteotomy, peroneal nerve neurolysis creates a working space for the osteotomy by retracting the peroneal nerve. Fibular osteotomy before PLOWHTO must be performed just below the fibular head because the crural interosseous membrane stabilises the positional relationship between the tibia and fibula (figure 6C). The crural interosseous membrane makes it challenging to open the gap if fibular osteotomy is performed at the midportion of the fibula (figure 6A,B). In medial OWHTO, the PTFJ stabilises the osteotomy site, even if a type I hinge fracture occurs (figure 6D).²⁴ In addition, in hybrid closed-wedge HTO, the medial collateral ligament acts as a tension band, leading to medial stability (figure 6E).²⁵ However, in PLOWHTO, there is no stabilising effect on the anteromedial aspect of the osteotomy site, which leads to instability following a hinge fracture (figure 6F,G). Therefore, temporary anteromedial plate fixation was necessary before opening the posterolateral gap (figure 6H). Attention to these critical factors can help reduce the risks of intraoperative and postoperative complications.

Although this is a report of a single rare case and its short-term outcome, PLOWHTO can be applied to cases of tibial plateau fractures with lateral tibial dysplasia. However, it remains unknown whether patients need to undergo additional surgery in the long term. Segmental osteotomy of the fibula might

cause deformity of the tibia in the long term owing to the lack of support of the fibula. As segmental osteotomy of the fibula can shorten the course of the peroneal nerve, we performed segmental osteotomy in this case. Although the short-term clinical outcomes were favourable, further follow-up is required.

In conclusion, we performed a novel osteotomy adapted to the patient's pathology and deformity in a young patient with genu valgum due to EDS, which led to good short-term outcomes. PLOWHTO is considered a valuable surgical technique when performed with attention to pitfalls.
