Summary

There are many similarities between mycobacteriosis, in particular, tuberculosis, and sarcoidosis such as predominant intrathoracic localisation (even if all organs and tissues may be concerned), great variability of phenotypic expression, and granulomatous inflammatory reaction, caseous necrosis not being an absolute criterion of tuberculosis. Moreover, microbial (or mycobacterial?) agents may play a role in the pathogenesis of sarcoidosis which remains a diagnosis of exclusion particularly in atypical cases.

The authors report a case of a non-immunocompromised female patient who presented, simultaneously, isolated axillary tubercular adenitis and neuro-sarcoidosis without any other localisation. This case illustrates the difficulty to distinguish between both of these two diseases and thus to choose an adequate treatment when diagnosis is not proven. Moreover, our patient (human leucocyte antigen B27 positive) presented symptoms of spondylarthritis which also may have a nosological link with tuberculosis or sarcoidosis.

BACKGROUND

There are many similarities between mycobacterial infections, in particular, tuberculosis, and sarcoidosis, such as predominant intrathoracic localisation (about 90%), even given that all organs and tissues may be concerned, great variability of phenotypic expression, and granulomatous inflammatory reaction, caseous necrosis not being an absolute criterion of tuberculosis. Moreover, microbial (or mycobacterial?) agents may play a role in the pathogenesis of sarcoidosis, which remains a diagnosis of exclusion, particularly in atypical cases.

Figure 1 Ziehl stain (axillary adenopathy).
We report a case of a non-immunocompromised female patient who presented, simultaneously, isolated axillary mycobacterial (tuberculous?) adenitis and neuro-sarcoidosis without any other localisation. This case illustrates the difficulty in distinguishing between these two diseases and thus in choosing an adequate treatment in the absence of diagnostic proofs. Moreover, our patient (human leucocyte antigen (HLA) B27 positive) presented symptoms of spondylarthritis which may have a nosological link with sarcoidosis.

**CASE PRESENTATION**

A 50-year-old caucasian woman consulted for nodular erythema, arthralgia of ankle and isolated axillary adenopathies which already had occurred 3 months before, persisting after antibiotic treatment which had been administered after withdrawal of a foreign body on a homolateral finger tip. Three weeks before the first occurrence of adenopathies, she had travelled to Cairo for 4 days; there was not any known contact with tuberculosis. Moreover, she was suffering from diarrhoea and inflammatory spine and heel pain. Her medical history included benign breast tumour, hysterectomy and smoking; two members of her family had HLA B27 positive spondylarthritis. Physical examination was normal besides left axillary adenopathy of 20 mm.

**INVESTIGATIONS**

Biological screening revealed a mild inflammatory syndrome and a slight elevation of ACE; none of the serologies was in favour of acute bacterial or viral infection, in particular, serologies of HIV and bartonella were negatives, serologies of Epstein–Barr virus, cytomegalovirus and toxoplasmosis revealed acquired immunity, and there was no evidence of fungal infection. Autoimmune diseases could be ruled out biologically. HLA B27 was positive, intradermal tuberculin test at 10 mm. Spine x-ray and colonoscopy were normal as well as CT body scan, besides two left axillary lymph nodes. Lymph node cytodiagnosis showed adenitis but all microbial cultures were negative, whereas on microbiopsy, granulomatous, gigantocellular and necrotising adenitis was found but neither caseous necrosis nor positive Ziehl coloration was present. Cultures of mycobacteria remained negative. Surprisingly, a second analysis of the axillary lymph node, performed several months later, revealed the presence of acid-alcohol resistant bacilli (AARB) by a positive Ziehl stain (figure 1).

**TREATMENT**

Inspite of the lack of proof for tuberculosis upon initial investigations, patient received a classical antituberculous treatment for a period of 6 months. In the following weeks, increasing back pain incited to start a treatment of spondylarthritis by a disease modifying antirheumatic drug (sulfasalazidine). This treatment was of no benefit but gave rise to a DRESS syndrome (drug reaction with eosinophilia and systemic symptoms) which developed favourably under high dose dexamethasone.

**OUTCOME AND FOLLOW-UP**

Later on, patient presented asthenia, hormonal analysis revealing suprarenal insufficiency of central origin. But
asthenia persisted in spite of hydrocortisone replacement therapy, and slight transitory facial paralysis occurred. At this time, MRI of the brain revealed signs of inflammation in the stalk of pituitary gland and at the bottom of the third ventricle (figures 2 and 3), and ACE level in cerebrospinal fluid (CSF) was at twice the normal upper value. Hence neurosarcoidosis was diagnosed, even if complete screening for other localisations of sarcoidosis (CT body scan, cardiac MRI, salivary gland biopsy) remained negative. High dose oral corticotherapy (prednisone) was begun at 1 mg/kg/day, associated with methotrexate at 20 mg/week intramuscular 3 months later. Patient felt much better and was able to take up a half time job again. Prednisone doses could be lowered by 2.5 mg steps every 2 weeks but relapse of asthenia occurred at a 7 mg daily dose of prednisone, inciting to re-increase doses slightly. Nevertheless, at 18 months, immunosuppressive treatment had to be considered as insufficient, clinical signs persisting at prednisone doses at more than 10 mg/day. Moreover, she presented intense inflammatory spine pain at prednisone doses beneath 12 mg/day, in the context of spondylarthritides. Hence, methotrexate was replaced by mycophenolate mofétil 2 g/day and hydroxychloroquine 400 mg/day (the latter being rapidly stopped because of ophthalmologic side effects).

Actually, at 20 months of treatment for neurosarcoidosis, asthenia is very fluctuating and may be partially linked to dysthymic disorders (depression) and hormonal imbalance (menopause). Moreover, sleep apnoea syndrome has been discovered recently but treated adequately.

**DISCUSSION**

In spite of the absence of AARB on initial analysis of biopsy of the adenopathy, and mycobacterial culture remaining negative, we betted on tuberculous adenitis and treated upon this hypothesis. Indeed, the probability of adenitis by mycobacterium avium complex is very low in immunocompetent and adult patients, and in principle, our patient had no risk of developing mycobacterium marium infection. By the way, OMS recommendations allow the diagnosis of tuberculosis in the sole presence of AARB. In tuberculosis, extrapulmonary localisations are found in 10 to 25 % of all cases, more than half of them being situated in the lymph nodes. In a series of 636 cases, only 10 presented isolated axillary tuberculous adenopathy. Differential diagnosis of axillary adenopathy includes sarcoidosis, lymphoma, breast cancer and infectious diseases such as bartonella. Concomitant breast cancer and axillary tuberculosis have been described.

Like tuberculosis, sarcoidosis is intrathoracic in up to 90% of all cases. Extrathoracic localisations occur in about 20% and up to 50% in older patients, their incidence being yet higher in series of autopsies. All tissues and organs may be affected. A majority of these patients have simultaneous thoracic sarcoidosis or typical clinical manifestations of sarcoidosis but isolated extrathoracic forms may be very difficult to identify as sarcoidosis. Even biopsy, to be performed whenever possible, may not always allow establishment of diagnosis. The American Thoracic Society/European Respiratory Society/World Association of Sarcoidosis and other Granulomatous consensus requires convergence of a compatible clinical, radiological and...
biological presentation, the presence of typical granuloma and the absence of other types of granulomatosis. Thus, sarcoidosis is to be a diagnosis of exclusion. Some malignant lesions or tuberculosis can mimic lesions of sarcoidosis and can occur simultaneously or successively. Moreover, implication of mycobacteria or propionibacteria has been discussed in the pathogenesis of sarcoidosis.

Incidence of neuro-sarcoidosis is estimated between 5 and 25% but only 10% of these patients have no other localisation. It is twice as high in series of autopsies, remaining without clinical manifestations in many cases. It is presented as meningitis, invasion of the hypothalamus, the pituitary gland or cranial nerves, or as tumour lesions. ACE in CSF is elevated in only 33% of neurosarcoidosis cases. A biopsy can be realised in only 20% of neuro-sarcoidosis; nevertheless, it was difficult to establish diagnosis in the absence of other localisations and in the presence of concomitant tuberculosis.

Follow-up and evaluation of treatment of neurosarcoidosis is particularly difficult when clinical manifestations are non-specific like astheno- or dysthyemic disorders which may either be neuro-psychiatric symptoms of sarcoidosis, or reactionary. Moreover, in our patient, active spondylarthritides with inflammatory signs may contribute to asthenia as well and interfere with global clinical evaluation, and even with the choice of treatment modalities.

Several cases of spondylarthritides associated with sarcoidosis have been published. 14 of them were summarised in 2002. Spondylarthritides could be a rheumatologic phenotype of sarcoidosis, but presence of HLA B27 (our case, Connault et al.) is rather in favour of coincidence of two nosological entities.

Learning points
- Extrathoracic phenotypes of mycobacterial infections (in particular: tuberculosis) and sarcoidosis are not so rare and often very similar even if isolated axillary mycobacteriosis (tuberculosis) and isolated neuro-sarcoidosis are exceptional; they may constitute serious diagnostic problems in case of single localisations.
- In particular, isolated neuro-sarcoidosis needs to rule out any other differential diagnosis, therapeutic importance being important.
- Moreover, tuberculosis and sarcoidosis may occur successively or simultaneously; in passing, etiological pathologic links are discussed.
- Spondylarthritides may belong to extrathoracic sarcoidosis phenotypes.
