DESCRIPTION

A 77-year-old man presented to us with atypical chest pain, hypertension, hypercholesterolaemia and ST changes on the ECG lateral leads and negative cardiac enzymes. The presence of an intermediate pretest probability of coronary artery disease suggested performing a coronary tomography (CT). The scan documented calcium lesions in the left descending (Lad) and left circumflex coronary arteries and a saccular coronary artery aneurysm (CAA) adjacent to a calcium lesion in the Lad (figure 1, video 1). An invasive coronary angiography (ICA) demonstrated that only the calcium lesion adjacent to the CAA was associated with significant stenosis of the Lad. In this patient, degenerative, congenital, inflammatory, infectious, toxic and traumatic causes were excluded by laboratory investigations.

The frequency of CAA varies widely, from 0.3% to 5%, and complications include thrombosis, embolic phenomena, arteriovenous fistulisation, spasm, rupture with haemopericardium and sudden death.1 A prerequisite to CAA formation is the presence of erosion, ulceration and haemorrhage in the tunica media of the related vessel, while formation of a post-stenotic CAA is determined by turbulent blood flow, which causes wall damage.2,3 The patient’s setting suggested that the LAD post-stenotic CAA aetiology was a direct extension of the intimal atherosclerotic process in the tunica media of the vessel. An ICA revealed the severity of Lad obstruction, while CT displayed the CAA diameter and the exclusion of intraluminal thrombi. In this patient, combined CT and ICA were followed by successful aneurysm excision and surgical revascularisation of the Lad with an internal mammary artery.

Learning points

▸ Conventional coronary angiography may underestimate the size of the saccular coronary artery aneurysm (CAA) or not even detect the CAA if it is occluded or contains substantial thrombi or plaque. A combination of coronary tomography and invasive coronary angiography is therefore a determinant for saccular CAA detection.

▸ Conservative measures consist of attempts to prevent thromboembolic complications with anticoagulant therapy and administration of antiplatelet drugs.

Figure 1  (A) CTA shows a saccular coronary artery aneurysm in the left anterior descending (Lad) artery at the bifurcation of the first diagonal branch (D1) and a calcium plaque (red arrow) in the left circumflex artery. LM refers to the left main artery, and Ao refers to the aorta. (A1) Two calcium plaques in the Lad. The distal plaque is located in the neck of the aneurysm.
