Summary
Neonatal varicella infection is a rare condition since vaccine introduction. The authors report the case of a 12-day-old male who presented with a fever and generalized vesicular eruption. The patient’s mother had varicella infection 1 day before delivery without treatment. The neonate initially did not receive prophylaxis or treatment. He subsequently was started on intravenous acyclovir and recovered without further complications or sequelae. Prompt diagnosis and treatment for maternal prenatal varicella infection is necessary to prevent infection in the newborn, and healthcare provider awareness to avoid nosocomial transmission.

BACKGROUND
Neonatal varicella infection is a rare condition with an incidence of 2–6 per 100 000 live births per year. 1–3 Neonates born 2 days before or 4 days after the onset of maternal varicella can develop serious illness. Without treatment, the case death rate approaches 30%. 4 The American Association of Paediatrics recommends administration of varicella zoster immunoglobulin (VZIG) to newborns who

are born from mothers with a varicella infection 5 days before delivery and 2 days after delivery. We are presented an opportunity for healthcare provider education on the identification of varicella infections in adults and infants.

CASE PRESENTATION
A 17-year-old female, an indigenous minority (Shan) from Burma who has been living in Thailand for 15 years, G2P1001, with eight prenatal visits, and no problems during her previous pregnancy gave birth at 40 weeks by normal spontaneous vaginal delivery. She developed scattered vesicles on her trunk 1 day prior to delivery (figure 1). The rash subsequently extended to her face and extremities. She denied associated symptoms including fever, myalgias, cough, dyspnoea and urethralgia. She did not receive any treatment. After delivery the mother was separated from the baby for 2 days. She gave a history of a concurrent varicella infection of her nephew who stayed in the same house as her 3 days before she gave birth. Initial assessment on birth included Apgar scores of 10 and 10 (1 and 5 min respectively), birth weight of 2980 grams, length of 53 cm and head circumference of 33 cm.

Nine days after birth, the neonate was taken to a rural clinic in northern Thailand with a rash and fever for 3 days. He was prescribed amoxicillin syrup, but subsequently deteriorated. Three days later, he presented to the Chiang Mai University Hospital (CMUH) with an erythematous vesicular rash, which began on his face and subsequently extended to the trunk and extremities. Per the mother the neonate was irritable with a tactile fever, but did not have rhinorrhea, cough or diarrhoea. He was breastfed with normal oral intake and urine output.

On presentation to CMUH, the physical examination was remarkable for a temperature of 39°C, irritability, cluster of small shallow ulcers on erythematous base on the hard palate and generalised tense vesicles, with some areas of yellowish crusts, including the face, lips, genitalia, palms and soles (figure 2).

INVESTIGATIONS
Laboratory examinations were remarkable for haemoglobin (12.8%), haematocrit (37.5%) and total white blood

cell counts (8116 cells/ccmm, lymphocytes (48%)). Chest radiograph showed perihilar infiltrates (figure 3). Tzanck smear showed multi-nucleated giant cell (figure 4). Gram stain of lesion revealed numerous white blood cells with a predominance of neutrophils and gram positive cocci. Culture from skin lesion showed Staphylococcus aureus. Blood cultures were negative.

DIFFERENTIAL DIAGNOSIS
Neonatal varicella infection with secondary superimposed bacterial infection of the skin and pneumonia.

TREATMENT
The neonate was started on intravenous acyclovir (60 mg/kg/day) along with supportive therapies. Additionally, intravenous ampicillin and cefotaxime were also started empirically pending culture results.

OUTCOME AND FOLLOW-UP
The boy has completely recovered after treatment and was discharged home on day 14 with progressive resolution of rash (figures 5 and 6).

DISCUSSION
The first case report/review of neonatal varicella that we identified was from 1967, which reported a total of 34 cases from 1878 to 1965. A case series from 1988 to 1995 in Bangkok reported 26 cases of neonatal varicella, 12 infected perinatally and 14 postnatally, with the most common complications including pyoderma (55%), sepsis (30%) and pneumonia (26%). To our knowledge, this is the first case reported in Thailand outside of Bangkok.

Generally the diagnosis of varicella depends on a history of close exposure to an index case, and the characteristic vesicular rash and fever. This case brings up some interesting points. Often it is difficult to identify the source of infection. The mother’s exposure to her nephew with a possible varicella infection may have led her to contract the infection before delivery, but per report there was not a sufficient incubation period to explain transmission. We suspected that both the mother and her nephew might have been exposed to another unidentified index case during a similar period. Multiple provider-patient interactions occurred without recognition of the infection in the mother before and after delivery, and the neonate. This led to missed treatment with acyclovir for the mother, neonatal VZIG prophylaxis and early initiation of acyclovir treatment for the neonate. Additionally, because of this delay contact tracing did not occur. Once the varicella infection was identified, the neonate was treated promptly, isolated from others, and fortunately has not had identifiable sequelae. Subsequently, no new cases were identified.

Learning points
- Recognition of skin lesions, prompt diagnosis, treatment of pregnant women with varicella and neonatal prophylaxis are necessary to prevent neonatal varicella.
- Initial maternal treatment includes oral acyclovir within 24 h of onset of rash to decrease maternal symptoms and complications. If the maternal varicella rash develops 5 days before delivery or 2 days after delivery, VZIG should be administered for postexposure prophylaxis. Intravenous acyclovir may be used for prophylaxis if VZIG is not available or more than 96 h have passed since exposure.
- Neonates with suspected perinatal varicella exposure should receive VZIG.
- Neonatal varicella treatment includes intravenous acyclovir and supportive/symptomatic care is indicated, along with additional antibiotics if superimposed bacterial infection is suspected.
- A contact investigation should be conducted among all household members to identify immunocompromised individuals and need for post exposure prophylaxis.
