DESCRIPTION

A 74-year-old man was brought to emergency services when he was found lying unresponsive in his room. Nearest of the kin reported that his clothes were drenched with sweat and that he was a regular alcohol user who had consumed in excess the previous day. Vital signs were normal. There was decerebrate posturing of limbs with bilateral extensor plantar response. The doll's eye movement and corneal reflexes were preserved. There was no neck stiffness. Random blood sugar at admission was 34 mg/dl, which was corrected with 100 ml 25% dextrose bolus infusion which was maintained with dextrose infusion and glucagon 1 mg intramuscular as injection. His brain CT scan was normal. The spinal tap yielded normal results. The ECG, echocardiogram, four vessels Doppler neck including the aortic arch and Electroencephalogram were

normal. MRI of the brain showed hyperintense signals in both hippocampi, right insular, temporal, occipital and frontal cortex in diffusion-weighted images with diffusion restriction in apparent diffusion coefficient mapping suggestive of laminar cortical necrosis. MR angiogram was normal. He did not improve with treatment and succumbed to the illness (figures 1A, B, C and 2A, B, C).

First described in a patient with anoxic encephalopathy,¹ it was found later that laminar cortical necrosis represented cytotoxic oedema affecting a particular layer of cerebral cortex neuropathologically characterised by delayed selective neuronal necrosis and is a consequence of hypoxic-ischaemic encephalopathy, hypoglycaemic encephalopathy, status epilepticus and ischaemic stroke.² Mechanisms of laminar cortical necrosis are not well elucidated.

Figure 1 (A) Diffusion-weighted MRI shows linear hyperintensities in a gyral pattern in right parietal and insular cortices (white arrow). (B) MRI Apparent diffusion coefficient image showing hypointensities in these areas suggestive of restriction of diffusion. (C) Susceptibility weighted image shows hyperintensities within the right parietal and insular cortices without blooming artifacts.

Figure 2 (A) MRI coronal T2-weighted image of brain showing hyperintense signals from medial temporal lobe (thick white arrow) of right side sparing cerebellar hemispheres. (B) MRI FLAIR images showing hyperintensities in the hippocampal region and parahippocampal gyrus right more than the left. (C) MRI brain coronal section T2-weighted images showing hyperintensities bilaterally in the hippocampal region.

Learning points

- ▶ MRI finding of laminar cortical necrosis, even though first classically described in anoxic encephalopathy, simply represents cytotoxic oedema of varying aetiology and is a poor prognostic indicator.
- ▶ Hypoglycaemia disrupts protein synthesis in the superficial layers of the cortex, in the caudate, in the putamen and in certain cell populations of the hippocampus, whereas cerebellar and brain stem protein synthesis is relatively unaffected.³
- ▶ Cortical grey matter has six layers and of these three are most vulnerable to depletion of oxygen and glucose. Hypoglycaemic and hypoxic insult leads to death of neurons, glia, blood vessels and degradation of proteins.³
- ▶ Cerebral cortical laminar necrosis might be another clue for predicting the poor prognosis in an individual with hypoglycaemic insult.⁴

Competing interests None.
