Left circumflex arising from the right coronary artery and silent myocardial ischaemic damage: a potentially lethal disarray detected by cardiac CT and SPECT

Gian Piero Carboni,1 Pietro Sedati2

DESCRIPTION
In 2012 December, a 68-year-old man presented with mild effort dyspnoea, paroxysmal atrial fibrillation and type 2 diabetes. The ECG was within normal limits. Echocardiography documented septal and inferior left ventricle (LV) hypokinesia. Stress/rest technetium-99m sestamibi (MIBI)-gated, single-photon emission, cardiac tomography revealed septal and inferior wall defects with mild reversibility (figure 1) and reduced contractility. The submaximal exercise test was negative.1 2 Cardiac tomography documented an anomalous origin in the left circumflex artery (AOLCX) arising from the right coronary artery and coursing between the aorta and the left atrium (figures 2–4). Direct angiography excluded the presence of atherosclerotic disease. The systolic compression of the AOLCX produced by the aorta and left atrium during daily activities resulted in a transient reduction in coronary flow. The LV regional contractile anomalies were most likely a consequence of fibrotic myocardial damage due to brief but repetitive episodes of myocardial ischaemia.3 The absence

Figure 1 Stress/rest technetium-99m sestamibi (MIBI) single-photon emission cardiac tomography. Inferior (white arrows) and septal (green arrow) perfusion defects with mild reversibility. Polar maps better document the mild reversibility of the defects (red arrow).
of angina was likely due to the neuropathy caused by diabetes. The risk of sudden death (SD) has been reported in patients with AOLCX. However, an ectopic left coronary artery is more likely to cause SD due to the greater ischaemic territory involved. Moreover, this risk decreases with age. In this patient, the combination of fibrosis, ischaemia and normal tissue may imply electrical instability and life-threatening arrhythmias due to enhanced automaticity, triggered activity or re-entry. As the ischaemia was mild, surgery was not indicated and the β-blocker dose was increased to provide greater myocardial protection.

**Learning points**

- A negative submaximal exercise test is a frequent finding in patients with congenital coronary anomalies.
- In the temporal sequence of the pathophysiological cardiac changes that culminate in ischaemia, abnormal myocardial perfusion on single-photon emission cardiac tomography (SPECT) imaging precedes ST-segment depressions on an exercise test. Compared to an exercise test, SPECT imaging has greater diagnostic capacity for identifying myocardial ischaemia.
- Cardiac CT has been established as an excellent non-invasive test to identify and classify congenital coronary artery anomalies.

**Contributors**

GPC was involved in writing the manuscript. PS performed the CT imaging and was involved in revision of the manuscript. Both the authors approved the final version of manuscript to be published.

**Competing interests**

None.

**Patient consent**

Obtained.

**Provenance and peer review**

Not commissioned; externally peer reviewed.
