DESCRIPTION

An 18-year-old male patient suffered from painful oral ulcers, causing 10 kg body weight loss. The dermatologist diagnosed him with pemphigus, based on the clinical characteristics of the ulcers. Owing to the weight loss an abdominal mass became palpable. On CT (figure 1) a large hypervascular heterogeneous solid mass was found, with central calcifications (maximum diameter 20 cm). Percutaneous biopsy revealed an inflammatory myofibroblastic tumour (IMT). Pemphigus was interpreted as paraneoplastic symptom.

Owing to the hypervascularised nature of the tumour on CT, 5 days before surgery selective embolisation of the major arterial blood suppliers was performed by percutaneous angiography. En bloc resection of the tumour, left kidney and a small part of the left adrenal gland (figure 2) was performed with minimal blood loss.

The pathologist found a radically excised 19 cm IMT, with negative staining for anaplastic lymphoma kinase (ALK gene).

Paraneoplastic pemphigus is mostly associated with haematological malignancies; it is only rarely seen with non-haematological neoplasms, such as IMT.¹ IMTs are neoplasms of intermediate biological potential, composed of myofibroblastic mesenchymal spindle cells accompanied by an inflammatory infiltrate. ALK gene rearrangements are present in up to 70% of IMTs. The most common sites of origin are the abdominopelvic region, lung, mediastinum and retroperitoneum. They frequently recur locally (especially when located in the abdominopelvic region), but rarely metastasise. The latter is most often seen in ALK-negative tumours.² Tumour excision with wide margins is indicated to minimise the chance of local recurrence.³ Time course and pattern of development of distant metastases is not well described in the literature. Owing to the high risk for recurrence, regular clinical follow-up of patients after local resection of IMT is advised. After 2 years of follow-up there were no signs of recurrence in this patient. The paraneoplastic pemphigus is in remission after radical tumour removal and adequate immunosuppressive drug therapy.¹

Figure 1 (A) Coronal view of the preoperative CT of the abdomen, showing a large hypervascular inhomogeneous solid tumour in the left hemiabdomen, with central calcifications (see white spots in the tumour), measuring 20×9×11 cm. Multiple arterial suppliers and venous structures are detected, with a maximum diameter of 2.2 cm (indicated by the arrow). The tumour is possibly invading the left kidney, and is located against the spleen and psoas muscle. Furthermore, the tumour causes shift of the ascending colon and small intestine. There are no pathologically enlarged lymph nodes or signs of distant metastasis. (B) Coronal view of a vascular subtraction reconstruction of CT of the abdomen, illustrating the hypervascular state of the inflammatory myofibroblastic tumour.

Figure 2 (A) In vivo image of the solid tumour with a clear exposure of a large vascular structure (indicated by the arrow). (B) Surgical specimen: en bloc resection of the tumour, left kidney and a small part of the left adrenal gland.

Learning points

- ▶ Pemphigus can present as a paraneoplastic symptom in patients with inflammatory myofibroblastic tumour (IMT).
- ▶ IMTs are neoplasms, which frequently tend to recur locally, but rarely metastasise; absence of anaplastic lymphoma kinase gene activity seems to increase the risk of distant metastasis.
- ▶ With proper preoperative workup, even in hypervascularised tumours, radical resection with minimal blood loss is feasible and indicated for local control.
