CASE REPORT

Omental torsion, a rare cause of acute abdomen
Shivani Joshi,1 Gary Andrew Cuthbert,2 Rajab Kerwat2

SUMMARY
Omental torsion is a rare cause of acute abdominal pain. We report a case of omental torsion in a 7-year-old girl who presented with right iliac fossa pain. The patient underwent an open appendicectomy, during which a normal appendix was identified and a diagnosis of omental torsion was made. The affected segment of omentum was resected along with the appendix. The patient made an uncomplicated recovery and was discharged on day 1 postoperatively. A normal appendix in the presence of omental torsion is found in 0.1% of all appendicectomies in children. We suggest routine visualisation of the omentum in the presence of a normal appendix during appendicectomy.

BACKGROUND
Eitel first described primary omental torsion in 1899.1 There have not yet been any definitive guidelines to aid diagnosis. Reported cases describe characteristic appearances on radiological imaging; however, surgical exploration remains the definitive gold standard for intraoperative diagnosis and therapeutic management. Increased awareness of omental torsion as a differential diagnosis for acute abdominal pain will encourage routine inspection of the omentum intraoperatively. It may act to advocate the use of laparoscopy in suitable patients, in order to take advantage of its diagnostic value in exploring the abdominal cavity in the presence of a normal appendix.

CASE PRESENTATION
A 7-year-old girl was admitted to the local accident and emergency department, reporting acute onset of localised non-migratory right-sided abdominal pain and fever, for which she had been sent home from school the same day. The pain was not eased by paracetamol, and accompanying symptoms included fevers, rigours and dysuria. There was no significant anorexia, nausea or vomiting. The patient did not report any upper respiratory tract symptoms or change in bowel habit. Her medical history included a full term normal vaginal birth, with no history of childhood illness or surgery. She was of normal body mass index and had up-to-date vaccinations.

The patient was referred by the paediatricians to the surgical team. On examination of the vital signs, she was normotensive, but feverish (38.0°C) and tachycardic (151 bpm). On examination of the abdomen, she was noted to be tender over the right iliac fossa, with localised rebound tenderness and guarding. Examinations of the remaining systems were unremarkable. Additional examination of both hips confirmed no bony tenderness, and no pain on active or passive movements.

INVESTIGATIONS
Routine bloods on admission showed a moderate leucocytosis; a white cell count of 18.1×109/L, neutrophils of 13.4×109/L and a C reactive protein of 51 mg/L. A urine dipstick was found to be negative for nitrates, blood, protein and white cells, ruling out urinary tract infection as a possible cause for her symptoms.

A clinical diagnosis of acute appendicitis was made by the surgical team, with a plan to proceed with open appendicectomy. Imaging was not deemed necessary given the strong clinical evidence supporting a diagnosis of appendicitis. However, if the presentation had been less tangible, an ultrasound could have been offered to aid preoperative diagnosis.

DIFFERENTIAL DIAGNOSIS
The differential diagnoses considered in this case by the surgical team included acute appendicitis, Meckel’s diverticulum, mesenteric adenitis and ovarian pathology.

Right iliac fossa pain in a premenarche female, with associated leucocytosis, fever and vomiting, is often a classical presentation of acute appendicitis, and is treated by an appendicectomy; this remains the most common cause for emergency surgery today, via either laparoscopy or open technique.

Intraoperatively, when no inflammation is found surrounding the appendix, it is routine to check for other pathology, such as Meckel’s diverticulum. Meckel’s diverticulum is a congenital bulge found in the terminal ileum two feet proximal to the ileocaecal valve, representing a vestigial remnant of the omphalomesenteric duct.2 It is present in approximately 2% of the population and is mostly asymptomatic; however, if symptomatic, it commonly occurs before the age of 2 years, presenting typically with painless rectal bleeding and right iliac fossa pain mimicking that of acute appendicitis.3 Definitive treatment of a symptomatic Meckel’s diverticulum would involve surgical excision of the diverticulum with or without the adjacent ileal segment.2

In this patient, the presence of a normal appendix and terminal ileum on inspection ruled out these differentials as a cause for her abdominal pain. Other possible paediatric causes of right iliac fossa pain in the presence of a normal appendix include mesenteric adenitis, urinary tract infection and ovarian pathology. Mesenteric adenitis involves inflammation of the mesenteric lymph nodes, typically causing pain in the right iliac fossa.4 It is
differentiated by preceding symptoms of upper respiratory tract infection.

The most common ovarian pathologies seen in paediatric females are ovarian cysts or less commonly, malignant neoplasms. The diagnosis would normally be made by preliminary imaging or at diagnostic laparoscopy.7

Omental torsion is a rare differential for acute abdominal pain, clinically mimicking acute appendicitis—presenting typically with constant non-radiating pain in the right iliac fossa, and occasionally with associated low-grade fevers, moderate leukocytosis and vomiting. Fifty per cent of patients are found to have omental torsion present with an abdominal mass and localised peritonitis.5 They are found to be less systemically unwell than those with acute appendicitis,6 although most diagnoses are made intraoperatively in the presence of a normal appendix.

TREATMENT

This particular case took place in a district general hospital lacking specialist paediatric services. On the basis of clinical signs and laboratory investigations, there was a high clinical suspicion of acute appendicitis. A decision was made to proceed with appendicectomy. The first steps in management were intravenous fluids and antibiotics. The patient was kept nil by mouth and preparations were made for theatre. The team proceeded with an open appendicectomy via a Lanz incision. On exploration, the appendix was normal in the presence of a patch of torted ischaemic appendicitis.7

The use of laparoscopy confers various benefits including a reduction in postoperative pain, shorter hospital stays and a reduced incidence of wound complications and scarring. The disadvantages include loss of touch sensation, difficulty in controlling bleeding and a two-dimensional image.9 In this circumstance, patient safety being of utmost importance, the skill and preference of the operator was considered and after discussion with the family, the decision was made to proceed with an open procedure.

OUTCOME AND FOLLOW-UP

The histology from the omental section showed focal necrosis of the omentum with acute inflammation and haemorrhage consistent with torsion. The sections from the appendix were consistent with periappendicitis plus inflammation of the serosa. There was no evidence of acute suppurative appendicitis.

The patient remained haemodynamically stable and afebrile throughout her recovery and was discharged the following day. Further follow-up was not required.

DISCUSSION

The greater omentum, embryologically, is derived from the dorsal mesentery. It is a sheet consisting of four layers of peritoneum, suspended from the greater curvature to cover the surrounding organs.1

Omental torsion occurs as the omentum twists around a pivotal point on its long axis. The most common point of torsion is around the distal right epiploic artery due to the increased length and mobility on the right side of the omentum.1 This results in venous obstruction, causing further oedema and vascular compromise, consequently leading to necrosis and adhesion formation.10

Omental torsion can be primary or secondary. Primary torsion forms one-third of cases, with no underlying causative pathology or distal fixation.6 Precipitating factors include trauma, obesity and sudden changes in body position or excessive exertion, that lead to an increase in abdominal pressure.10 Secondary causes can include adhesions from previous surgeries, hernias and other foci of inflammation.11 These cause a distal fixation, resulting in bipolar torsion.12 In extremely rare cases, the omentum has been noted to infarct without any evidence of torsion, a phenomenon known as primary idiopathic segmental infarction.13

Since the first diagnosis of omental torsion by Eitel in 1899, primary omental torsion has been found in 1% of appendicectomies carried out for suspected appendicitis in children.14 Patients typically present with non-radiating pain in the right iliac fossa and a moderate leukocytosis. There is often associated low-grade fever, anorexia, nausea or vomiting. Fifty per cent of patients with large segment involvement are found to have a palpable mass on abdominal examination, with localised peritonitis.5 Retrospective studies have shown that patients found to have omental torsion have been less systemically unwell compared to those with acute appendicitis.6 Patients typically present within the third to fifth decades, with a slightly higher prevalence in males (3:2).6

In cases where the clinical picture is equivocal, ultrasound and CT have been shown to have a role in diagnosis.10 CT scans in positive cases typically show hyperattenuated streaks of fat beneath the parietal peritoneum in the affected segment, with associated thickening of the overlying anterior abdominal wall.5 There is often a characteristic whirling pattern of the mesentery, with an accumulation of serosanguinous fluid within the peritoneum.5 Ultrasound imaging is useful in cases presenting with a palpable mass. A hyperechoic, non-compressible mass is typically shown with localised point tenderness.10

Figure 1 The congested, torted omentum on a narrow pedicle, delivered through the incision site prior to resection.
Diagnostic laparoscopy in suitable patients remains the investigation of choice for patients with atypical presentations, allowing intraoperative diagnosis and treatment. However, it has been argued that laparotomy should be the definitive method for omental excision. Findings include an infarcted segment of omentum and, often, a large volume of sterile, serosanguinous fluid within the peritoneal cavity, due to haemorrhagic extravasation. The normal appendix is usually removed to prevent future difficulties in diagnosis.

Our recommendation for appropriate surgical management is routine inspection of the omentum in the presence of a normal appendix and terminal ileum. Visualisation of the omentum via a Lanz incision can be challenging in overweight children and adolescents. In these patients, a move towards laparoscopy will improve the chances of making accurate diagnoses.

**Learning points**

- Increased awareness of omental torsion as a differential diagnosis for acute abdominal pain is needed.
- Routine inspection of the omentum in the presence of a normal appendix during appendicectomy is required.
- It is important to acquire preoperative imaging when appropriate.
- The diagnostic value of laparoscopy in patients with equivocal clinical signs is highlighted.
