DESCRIPTION

A 72-year-old patient with a history of chronic obstructive pulmonary disease (COPD) and hepatitis B, presented to the emergency room, with abdominal pain that had started 6 h previously, accompanied by nausea, vomiting and a 38.8°C fever. Clinical examination revealed generalised peritonitis. Lab results showed increased C reactive protein at 66 mg/L (normal value <7.5) and leucocytosis at 21.6 giga/L (normal value 4.0–10.0).

Abdominal X-ray showed signs of colic pneumatosis (figure 1). This was confirmed by CT scan, which also showed the existence of a discreet pneumoperitoneum and the presence of a moderate amount of free fluid (figure 2).

In view of this clinical and paraclinical picture, an explorative laparotomy was performed, revealing widespread colic pneumatosis starting at the caecum and extending all the way to the sigmoid (figure 3). The presence of cloudy peritoneal fluid was also noted. A careful examination of the bowels was performed, but no perforation was found. A subtotal colectomy with mechanical ileo-sigmoid anastomosis was performed. An ulcerative-like perforation was discovered in the transverse colon during postoperative examination of the specimen (figure 4A,B). The final diagnosis after pathological examination was determined to be pneumatosis cystoides intestinalis with one ulcerative-like ischaemic perforation. The patient made an uneventful recovery and was discharged on day 7.

Pneumatosis is a rare disease characterised by the presence of gas in the submucosa and subserosa of the bowel. In a retrospective review published by Koss1 in 1952, 15% of cases of pneumatosis intestinalis were classified as primary or idiopathic, and 85% were considered secondary. Traditionally, pneumatosis intestinalis was considered to require operative treatment, however, Morris2 reports that up to 50% of cases can be managed non-operatively. Surgery is advised in cases presenting...
with obstruction or acute abdomen. In the patient described here, operative treatment was planned based on the clinical picture and the presence of free fluid.

Learning points

▸ Management of pneumatosis intestinalis can be operative or conservative, the decision should be based on the clinical and radiological pictures.
▸ Surgical management is normally required in the presence of an acute abdomen.
▸ Most cases of pneumatosis intestinalis are secondary to other pre-existing pathologies.
