DESCRIPTION
The pseudoaneurysms of the radial artery are uncommon, generally secondary to trauma or invasive procedures such as arterial catheterisation (0.09%).1 2 Predisposing factors are advanced age, longer duration of catheterisation, coagulation disorders or use of anticoagulants/antiplatelet agents. A woman of 85 years, with history of ischaemic heart failure, chronic atrial fibrillation on anticoagulation, with labile International Normalisation Ratio, hypertension, peripheral artery disease and dyslipidaemia, was admitted in the context of acute pulmonary oedema secondary to hypertension, requiring hospitalisation in intermediate care unit and continuous arterial catheterisation. Seventeen days after removal of arterial line, a palpable pulsatile mass, soft, painless and without other inflammation signs was found at the site of palpation of the right radial artery, where previously the arterial catheter had been inserted (figures 1A, B). Further investigation by Doppler ultrasound (figure 1C) identified a pseudoaneurysm of the radial artery, >2 cm in diameter, which was lap-permeable and non-thrombosed. No other complications, such as neurapraxia, compartment syndrome, rupture or haemorrhage were found until 38 days after diagnosis, when the patient was submitted to surgical removal of the false aneurysm and direct arteriorrhaphy, uneventfully (figure 2). To date, the patient is asymptomatic, with no evidence of any complication.

Learning points
▸ Illustrates a rare complication of a procedure commonly performed by the internist.
▸ Recalls the possibility of late development of pseudoaneurysm after arterial catheterisation.
