DESCRIPTION

A Caucasian woman aged 67 years presented to our outpatient clinic with an 18 months history of asymptomatic continuously progressing longitudinal brown bands on her toenails. There was no history of trauma or friction to her toenails. She was ineffectively treated with oral terbinafine for 3 months due to suspected onychomycosis. Since 3 years, she received treatment for polycythaemia vera with hydroxyurea in varying doses ranging from 500 to 1500 mg daily. Her polycythaemia vera was adequately regulated. She experienced no other side effects. Her medical history was otherwise unremarkable. Family history was negative for longitudinal melanonychia and melanoma.

Physical examination showed multiple longitudinal brown-pigmented bands on eight toenails with subungual hyperkeratosis. Pseudo-Hutchinson’s sign was present as the pigmentation extended proximally beneath the translucent cuticles, but the cuticles and nail folds were not affected (figures 1 and 2A). Her fingernails were normal. No other mucocutaneous pigmentation was seen.

The differential diagnosis of longitudinal melanonychia affecting multiple nails consists of an iatrogenic cause like drug-induced hyperpigmentation, physiological, repetitive trauma, subungual haematoma, onychomycosis, pseudomonas infection or underlying systemic disease. Subungual melanocytic naevus or melanoma were unlikely as multiple nail units were affected. Subungual melanoma was also unlikely due to the absence of micro-Hutchinson’s sign and Hutchinson’s sign. Our patient was diagnosed with a drug-induced melanonychia caused by hydroxyurea.

She requested temporary discontinuation of the drug as she experienced cosmetic inconvenience due to the discoloured toenails. Already 6 weeks after discontinuation, outgrowth of the brown bands was visible with significant lightened brown colouring of the pigmentation (figures 1 and 2B). The patient was unable to suspend the drug permanently.

Melanonychia are an uncommon side effect of hydroxyurea. This is a cytostatic drug used for management of myeloproliferative disorders. Melanonychia develops in about 4.3% of the patients receiving hydroxyurea therapy.1 The onset of the melanonychia varies from 4 weeks to 5 years after initiation of the hydroxyurea.2,3 This case demonstrates that an iatrogenic (drug-induced) cause should be considered in the case of longitudinal melanonychia affecting multiple nails. Malignant melanoma should be considered and ruled out in the case of a single affected nail. Hutchinson’s sign and micro-Hutchinson’s sign are important clinical clues.

Figure 1 Multiple longitudinal brown bands on the toenails of digiti I–III of the right foot during treatment with hydroxyurea (A) and 6 weeks after discontinuation of hydroxyurea (B).

Figure 2 Multiple longitudinal brown bands on all the toenails of the left foot during treatment with hydroxyurea (A) and 6 weeks after discontinuation of hydroxyurea (B).
Learning points

- In the case of longitudinal melanonychia of multiple nail units, an iatrogenic cause should be considered. The most important cause is the use of (cytostatic) drugs.
- Melanonychia are a rare side effect that occurs in about 4.3% of patients receiving hydroxyurea therapy.
- Longitudinal melanonychia can extend beneath the translucent cuticle without involving the cuticle or nail fold, which is considered a pseudo-Hutchinson’s sign.
- Micro-Hutchinson’s sign is present when a hyperpigmentation in the cuticle is only visible on dermoscopy. Hutchinson’s sign is a macroscopic nail pigmentation extending into the cuticle and nail fold. Both are important clinical clues for subungual melanoma.

Hutchinson’s sign is characterised by a macroscopic hyperpigmentation of the cuticle and adjacent nail fold. Micro-Hutchinson’s sign is present when a hyperpigmentation is limited to the cuticle, but is only visible on dermoscopy and not with the naked eye. Longitudinal melanonychia can be associated with a hyperpigmentation that extends beneath the translucent cuticle, without involving the cuticle and/or nail fold. This hyperpigmentation simulates micro-Hutchinson’s sign, but is in fact a pseudo-Hutchinson’s sign of the illusory type, that is visible due to transparency of the cuticle. Antimycotic treatment is not useful. After discontinuation of the inducing drug, the melanonychia will disappear as the nail grows.

Contributors ALN, CCWT and JEK all made substantial contributions to conducting, reporting, conception, design, analysis and interpretation of the case report. ALN, CCWT and JEK also drafted the article and revised it critically for important intellectual contact and gave final approval of the submitted version.
