CASE REPORT

Fulminant myocardial bleeding: another clinical course of vascular Ehlers-Danlos Syndrome

SUMMARY

Vascular Ehlers-Danlos Syndrome (vEDS) is a dominantly inherited connective tissue disorder characterised by colon rupture and arterial aneurysm, dissection and rupture. A patient was diagnosed with vEDS after a spontaneous colon rupture when he was brought to our institute because of sudden chest pain. An ECG revealed wide regional ST elevation, which was initially suggestive of acute myocarditis. On the second day, haemodynamics suddenly deteriorated because of a rapid accumulation of bloody pericardial effusion, and the patient died. Autopsy revealed an excessive spontaneous myocardial haemorrhage owing to fragility, which suggested an underlying disease—vEDS.

BACKGROUND

Cases of fulminant myocardial bleeding and ischaemia are not frequently reported. To the best of our knowledge, only one fatal case of myocardial bleeding due to vascular Ehlers-Danlos Syndrome (vEDS) has been reported in the literature.¹ However, because it was a postmortem case, the clinical course of vEDS remained unknown.

CASE PRESENTATION

A 30-year-old man with chest pain was referred to our institute. He underwent repeated surgeries for spontaneous colon rupture. Five years after the surgeries, he was diagnosed with vEDS. His sister also underwent surgical repair due to arterial rupture. A novel heterozygous mutation at the donor-splice site in intron 23 (IVS23+1G>A) in the *COL3A1* gene was detected in the patient.

INVESTIGATION

On presentation to the emergency room, the patient's blood pressure was 98/60 mm Hg in both

arms. A physical examination revealed pallor, thin translucent skin and absence of heart murmur. An ECG showed a wide range of ST elevation (figure 1). Laboratory data revealed higher levels of troponin T and creatine kinase. An emergency coronary angiogram revealed no significant stenosis. Left ventriculography showed severe hypokinesis of segments 2 and 3. After admission to the intensive care unit, the patient suddenly suffered from cardiogenic shock due to cardiac tamponade (figure 2). No evidence of aortic aneurysm or dissection was documented by CT. Pericardiocentesis was performed, and a haemorrhagic effusion of 250 mL was identified. Percutaneous cardiopulmonary support was introduced because the patient showed sudden haemodynamic deterioration despite pericardiocentesis. Cardiopulmonary support was discontinued on the following day because the patient's haemodynamics stabilised and left ventricular wall motion improved. However, persistent ventricular fibrillation occurred, and the patient died 48 hours after admission. Autopsy revealed multiple epicardial and significant intramyocardial haemorrhages in all areas of the myocardial wall (figure 3); however, there were no significant findings in the coronary tree. Histopathological results revealed acute, widespread and generalised haemorrhages in the intramuscular layer and scattered myocardial lesions throughout myocardial walls without inflammatory cell infiltration (figure 4). There was no rupture or dissection in vessel walls; however, type 3 collagen tissues around vessel walls showed a thinner structure (figure 5).

DIFFERENTIAL DIAGNOSIS

The described clinical manifestations were compatible with progressive cardiogenic shock due to acute myocarditis, acute myocardial infarction or aortic dissection leading to cardiac tamponade and arrest. ECG findings indicated wide regional ST segment elevation, which indicated the presence of coronary artery disease. Coronary angiogram showed no evidence of acute coronary syndrome. Pericardiocentesis was then performed to treat cardiac tamponade. No evidence of aortic dissection or aneurysmal rupture was shown in the CT scan. We could not identify the clinical issue for differential diagnosis. Intramyocardial haemorrhages were finally identified in the autopsy.

DISCUSSION

Over two decades, the new international classification of EDS recognised 13 subtypes, which normally included all phenotypes presenting basic clinical hallmarks of EDS.² Of these subtypes, vEDS is an autosomal dominant hereditary connective tissue

Figure 4 Fragmentation of intramyocardial haemorrhage in myocardial tissues (H&E stain, ×200).

Figure 5 Microscopic examination of intramyocardial arterial (arrows) and venous (arrowheads) walls revealed that the amount of type 3 collagen was extremely low in our patient (left) than in the control (right) (× type 3 elastic-specific staining).

disorder caused by a structural defect in the pro α (1) chain of type 3 collagen encoded by *COL3A1*. Extensive bruising, spontaneous arterial rupture and a typical facial appearance are the predominant clinical manifestations.^{3,4} The cause of death is generally an accidental large arterial rupture. Major arterial complications related to a *COL3A1* mutation have also been reported.⁵ Type 3 collagen is a major protein in the walls of blood vessels and hollow organs, which explains the increased bruising, arterial and bowel fragilities and uterine, cervical and vaginal fragilities during pregnancy and delivery.⁶ This mutation can either cause decreased or no collagen synthesis or abnormalities in collagen secretion.^{7,8} Approximately, 50% of affected individuals have inherited the *COL3A1* mutation from an affected parent, while the other 50% have a de novo disease caused by a new onset of mutation.⁹ This case was identified in the *COL3A1* of the patient; however, Sanger sequence analysis confirmed that the apparently normal parents had no mutation. It is difficult to accurately assess the prevalence of vEDS, partly because of its rarity. A diagnosis is often made only after a catastrophic complication or during autopsy. Notably, the previously reported case is similar to the present case with respect to the sudden onset of symptoms and haemorrhage of intramyocardial capillary vessels. Although the aetiology is unclear, the spontaneous rupture of large arteries is typically associated with a fatal outcome caused by the fragility of blood vessels in vEDS. Previous studies have reported that CAG causes fatal damages of friable vessels characterised by multiple dissection.¹⁰ Autopsy revealed that the spontaneous haemorrhage of multiple intramyocardial capillary vessels resulted in a fatal outcome. There was no injury

Learning points

- ▶ This is the first reported case of catastrophic clinical manifestations due to myocardial bleeding without coronary artery disease in a patient with vascular Ehlers-Danlos Syndrome (vEDS).
- ▶ Skin elasticity may be the key for diagnosis, which can be identified during physical examination.
- ▶ Invasive examination should be performed with more consideration in the management of vEDS.
- ▶ This is a remarkable case in which vEDS is diagnosed from a patient with normal parents without gene mutation.

in any large vessels; therefore, this is an extremely rare cause of death. Notably, the fragility of small vessel walls may be associated with the haemorrhage of capillary vessels. Otherwise, there might be multiple vascular dissections that are not microscopically detected. Defects of the supporting type 3 connective tissue and interstitial collagen deficiency in small heart vessels could represent important issues in patients with vEDS. This has never been detected during the natural course of vEDS, characterised by fulminant myocardial bleeding that causes a tragic outcome in a young adult.

Acknowledgements We are grateful to Professor Kei Takahashi for the examination of the pathological tissue and for his helpful discussion. In addition, we would like to thank Dr Yoshinori Nagashima, Dr Megumi Minakawa and Dr Naohiko Sahara for their tremendous works on the management of the patient.

Contributors MT is the first author and the corresponding author too. HH was responsible for reviewing article and performed emergent coronary angiogram. KK was involved in the genetic screening. MN was responsible for the final approval of the version to be submitted.
