Intratesticular varicocele: a rare cause of male factor infertility

Ekta Dhamija, Chandan J Das, Abdul Razik

DESCRIPTION

A 27-year-old man who presented to the urology outpatient department of our hospital with primary infertility was referred for scrotal ultrasonography (USG). He had no scrotal pain, prior sexually transmitted diseases, scrotal trauma or surgery. Physical examination and blood investigations were normal. Semen analysis showed oligospermia (count of 10 million/mL) with a large fraction (>50%) of immobile sperms. B-mode USG revealed normal-sized bilateral testes; however, the left testis showed multiple hypoechoic testicular lesions along with minimal fluid in the scrotal sac (figure 1A). The intratesticular lesions were homogeneous in size and diffusely scattered throughout the left testis, radiating towards the mediastinum testis. All the lesions demonstrated spontaneous colour flow on Doppler imaging, which identified these lesions as dilated intratesticular veins (figure 1B). The imaging findings were consistent with intratesticular varicocele (ITV). No dilated vascular channels suggestive of extratesticular varicocele (ETV) were seen in the extratesticular soft tissue or along the spermatic cord. The patient was advised surgery which he refused.

ITV is a rare entity with incidence of 1.3%–2% in contrast to the much more common ETV, which occurs in 15%–20% of men.1 Most of the literature on ITV has been in the form of case reports or anecdotal case series. Pain has been documented as the most common presenting complaint (46%), followed by infertility (16%–21%).2 While most of the authors depicted left testicular involvement, Das et al showed no such predilection in their study of 25 cases.2 The fact that majority (72%) of ITV are associated with ipsilateral ETV has led to the hypothesis of common underlying pathophysiology. Hence, similar treatment techniques have been opted for both ETV and ITV with effective outcomes.

Learning points

- Intratesticular varicocele (ITV) is a rare cause of male factor infertility and is entirely a sonographic diagnosis.
- On ultrasonography, any dilated intratesticular venous structure showing reflux on Valsalva manoeuvre should be diagnosed as ITV.
- Early diagnosis is critical since prompt surgery results in excellent outcome. Once testicular atrophy sets in, chances of fertility diminishes.

On USG, ITVs are seen as cystic or tubular anechoic channels (>3 mm in size) radiating towards the mediastinum testis and showing prompt vascularity on colour Doppler. Secondary testicular atrophy is often present. Any intratesticular venous structure showing reflux on Valsalva manoeuvre should be considered as ITV, irrespective of the size. Anechoic cystic and hypoechoic lesions within the testis may represent tubular ectasia of rete testis, focal infection, haematoma or neoplasm. The characteristic imaging findings of spontaneous venous flow on colour Doppler and Valsalva manoeuvre determine the diagnosis of ITV and exclude other possible differentials. Patients with ITV are treated with surgical varicocelectomy or percutaneous embolisation. Adolescents with ITV should be treated with surgery as there is a higher risk of increasing testicular atrophy with time.3
