Neurocysticercosis: do not miss the eye

Deepanjan Bhattacharya,1,2 Asim Ghosh1

DESCRIPTION
A 6-year-old girl presented with new-onset left focal seizures, and was started on valproate. There was no history of fever, headache, visual deficit and neurological examination was completely normal. Neuroimaging revealed ring enhancing lesion in the right parietal lobe. Ocular examination revealed visual acuity of 6/6 in both eyes, with no evidence of uveitis or other abnormality of the anterior segment. Fundus examination revealed hypopigmented area in left retina midway between fovea and optic disc. Optical coherence tomography (OCT) using Spectralis HRA-OCT revealed presence of scolex beneath the retinal pigment epithelium (figure 1A). A Child was started on oral prednisolone and albendazole, and a 28-day course was completed. Repeat OCT revealed resolution of the scolex (figure 1B) and neuroimaging showed disappearance of the ring-enhancing lesion.

Cysticercosis is quite a common disease in tropical countries and is often difficult to diagnose. Demonstration of cysticercus by histology or subretinal parasite by funduscopy form absolute criteria for diagnosis of cysticercosis.1 Chavala et al reported a 25-year-old pork handler with intraretinal cysticercosis associated with vision loss, and ocular ultrasound revealing retinal detachment with hypoechoic focus, which responded to antihelminthic therapy.2 However, in the index case, there was no visual impairment, and response to therapy was excellent. OCT in suspected cases may be helpful in early detection as well as giving high-resolution images.

Learning points
► Ocular examination is of paramount importance in neurocysticercosis.
► Optical coherence tomography can diagnose lesions better with better resolution.
